A Phase-Locked Loop (PLL) is a crucial control mechanism in grid-connected inverter systems, ensuring proper synchronization with the grid. The role of PLL varies significantly between grid-forming and grid-following inverters. Application. Abstract—Microgrids are small-scale electricity supply networks that have local power generation. The general control philosophy within a microgrid is that sources must rely only on local information, yet. A phase-locked loop (PLL) is a control system that generates an output signal whose phase is fixed relative to the phase of an input signal. Keeping the input and output phase in lockstep also implies keeping the input and output frequencies the same; thus, a phase-locked loop can also track an. In this research, effective Phase Locked Loop (PLL) techniques for grid-forming (GFM) and grid-following (GFL) converters are designed to achieve a smooth transition from grid-tied to islanded mode of operation. In this work, PLL configurations are implemented while considering the active and. Phase-locked loop (PLL) circuits exist in a wide variety of high frequency applications, from simple clock clean-up circuits, to local oscillators (LOs) for high performance radio communication links, and ultrafast switching frequency synthesizers in vector network analyzers (VNA). For three-phase inverter, three sine wave references which are 120° phase separated are used.  $\omega$  is the angular frequency of the required output voltage.

A phase detector (PD) generates a voltage, which represents the phase difference between two signals. In a PLL, the two inputs of the phase detector are the reference input and the feedback from the VCO. The PD output voltage is used to control the VCO such that the phase difference between the two inputs is held constant, making it a negative feedback system.
